We study the effects of network topology on the response of networks of coupled discrete excitable systems to an external stochastic stimulus. We extend recent results that characterize the response in terms of spectral properties of the adjacency matrix by allowing distributions in the transmission delays and in the number of refractory states and by developing a nonperturbative approximation to the steady state network response. We confirm our theoretical results with numerical simulations. We find that the steady state response amplitude is inversely proportional to the duration of refractoriness, which reduces the maximum attainable dynamic range. We also find that transmission delays alter the time required to reach steady state. Importantly, neither delays nor refractoriness impact the general prediction that criticality and maximum dynamic range occur when the largest eigenvalue of the adjacency matrix is unity. © 2011 American Institute of Physics. [doi:10.1063/1.3600760]

Networks of coupled excitable systems describe many engineering, biological, and social applications. Recent studies of how such networks respond to an external, stochastic stimulus have provided insight on information processing in sensory neural networks.1,2 In agreement with recent experiments,3 these studies showed that the dynamic range of neural tissue is maximized in the critical regime, which is precisely balanced between growth and decay of propagating excitation. This regime was studied theoretically for directed random Erdős–Rényi networks in Ref. 1, where it was found to be characterized by a network mean degree equal to one. However, other studies4,7 showed that this condition does not specify criticality for other network topologies. In this paper, extending recent results, we present a general framework for studying the effects of network topology on the response to a stochastic stimulus. With this framework, we derive a requirement for criticality and maximum dynamic range that holds for a wide variety of network topologies. Moreover, we show that this prediction holds when refractory states and transmission time delays are included in the network dynamics, although other aspects of the response do depend on these properties.

I. INTRODUCTION

Many applications involve networks of coupled excitable systems. Two prominent examples are the spread of information through neural networks and the spread of disease through human populations. The collective dynamics of such systems often defy naive expectations based on the dynamics of their individual components. For example, the collective response of a neural network can encode sensory stimuli which span more than 10 orders of magnitude in intensity, while the response of a single neuron typically encodes a much smaller range of stimulus intensities. Likewise, the collective properties of social contact networks determine when a disease becomes an epidemic.

Recently, a framework to study the response of a network of coupled excitable systems to a stochastic stimulus of varying strength has been proposed. The Kinouchi–Copelli model1 considers the response of an undirected Erdős–Rényi random network of coupled discrete excitable systems to a stochastic external stimulus. A mean-field analysis of this model predicted1 that the maximum dynamic range (the range of stimuli over which the network’s response varies significantly) occurs in the critical regime where an excited neuron excites, on average, one other neuron. This criterion can be stated as the mean out-degree of the network being one, \( \langle d_{\text{out}} \rangle = 1 \), where the out-degree of a node \( d_{\text{out}} \) is defined as the expected number of nodes an excited node excites in the next time step (Ref. 1 refers to this quantity as the branching ratio).

Subsequent studies explored this system on networks with power-law degree distributions and hypercubic lattice coupling, and with a varying number of loops,2,4–7 showing that the criterion for criticality based on the network mean degree does not hold for networks with a heterogeneous degree distribution. However, these studies (except5) do not take into account features that are commonly found in real networks, such as, for example, community structure, correlations between in- and out-degree of a given node, or correlations between the degree of two nodes at the ends of a given edge.8 Furthermore, they do not consider the effect of transmission delays or a distribution in the number of refractory states.

---

†Electronic mail: daniel.larremore@colorado.edu.
In a recent report, we presented an analysis of the Kinouchi-Copelli model that accounts for a complex network topology. We found that the general criterion for criticality is that the largest eigenvalue of the network adjacency matrix is one, \( \lambda = 1 \), rather than \( \langle d^{\text{out}} \rangle = 1 \). While this improved criterion successfully takes into account various structural properties of networks, our analysis did not address the effect of delays or multiple refractory states, and was based on perturbative approximations to the network response. In this paper, we will extend the results of Ref. 2 by developing a nonperturbative analysis that accounts for distributions in the transmission delays and number of refractory states.

This paper is organized as follows. In Sec. II, we describe previous related work and the standard Kinouchi-Copelli model. In Sec. III, we present the model to be analyzed and derive a governing equation for its dynamics. In Sec. IV, we present our main theoretical results. In Sec. V, we apply our results to estimate the dynamic range of excitatory networks. In Sec. VI, we present numerical experiments to validate our results. We discuss our results in Sec. VII.

II. BACKGROUND

In this section, we describe the Kinouchi-Copelli model\(^1\) and other relevant previous work. In order to focus on the effects of network topology, the dynamics of the excitatory systems is taken to be as simple as possible. The model considers \( N \) coupled excitable elements. Each element \( i \) can be in one of \( m + 1 \) states, \( x_i \). The state \( x_i = 0 \) is the resting state, \( x_i = 1 \) is the excited state, and there may be additional refractory states \( x_i = 2, 3, \ldots, m \). At discrete times \( t = 0, 1, \ldots \), the states of the elements \( x_i^t \) are updated as follows: (i) If element \( j \) is in the resting state, \( x_j^t = 0 \), it can be excited by another excited element \( j, x_j^t = 1 \), with probability \( A_{ij} \), or independently by an external process with probability \( \eta \); (ii) the elements that are excited or in a refractory state, \( x_j^t \geq 1 \), will deterministically make a transition to the next refractory state if one is available, or return to the resting state otherwise (i.e., \( x_j^{t+1} = x_j^t + 1 \) if \( 1 \leq x_j^t < m \), and \( x_j^{t+1} = 0 \) if \( x_j^t = m \)).

For a given value of the external stimulation probability \( \eta \), which is interpreted as the stimulus strength, the network response \( F \) is defined in Ref. 1 as

\[
F = \langle f \rangle, \tag{1}
\]

where \( \langle \cdot \rangle \) denotes an average over time and \( f^t \) is the fraction of excited nodes at time \( t \). Of interest is the dependence of the response \( F(\eta) \) on the topology of the network encoded by the connection probabilities \( A_{ij} \). In particular, it is found that, depending on the network \( A \), the network response can be of three types: \( ^1, ^2 \) quiescent, in which the network activity is zero for vanishing stimulus, \( \lim_{\eta \to 0} F = 0 \); active, in which there is self-sustained activity for vanishing stimulus, \( \lim_{\eta \to 0} F > 0 \); and critical, in which the response is still zero for vanishing stimulus but is characterized by sporadic long lasting avalanches of activity that cause a much slower decay in the response, compared with the quiescent case, as the stimulus is decreased. Recent experiments\(^3\) suggest that cultured and acute cortical slices operate naturally in the critical regime. Therefore, the network properties that characterize this regime are of particular importance.

In Ref. 1, the response \( F \) was theoretically analyzed as a function of the external stimulation probability, \( \eta \), using a mean-field approximation in which connection strengths were considered uniform, \( A_{ij} = \langle d \rangle / N \) for all \( i,j \). It was shown that the critical regime is achieved at the value \( \langle d \rangle = 1 \), with the network being quiescent (active) if \( \langle d \rangle < 1 \) (\( \langle d \rangle > 1 \)). For more general networks (i.e., \( A_{ij} \) not constant), \( \langle d \rangle \) is defined as the mean degree (\( d = \frac{1}{N} \sum_i A_{ij} = \langle d^{\text{in}} \rangle = \langle d^{\text{out}} \rangle \)), where \( d^{\text{in}} = \sum_i A_{ij} \) and \( d^{\text{out}} = \sum_i A_{ji} \) are the in- and out-degrees of node \( i \), respectively, and \( \langle \cdot \rangle \) is an average over nodes. Such critical branching processes result in avalanches of excitation with power-law distributed sizes. Cascades of neural activity with power-law size and duration distributions have been observed in brain tissue cultures,\(^3,9–12\) awake monkeys,\(^1,10,13\) and anesthetized rats.\(^14–16\) While \( \langle d \rangle = 1 \) successfully predicts the critical regime for Erdős-Rényi random networks,\(^1\) it does not result in criticality in networks with a more heterogeneous degree distribution.\(^4,7\) Perhaps more importantly, previous theoretical analyses\(^1,4,7\) are not able to take into account features that are commonly found in real networks, such as, for example, community structure, correlations between in- and out-degree of a given node, or correlations between the degree of two nodes at the ends of a given edge.\(^8\) We will generalize the mean-field criterion \( \langle d \rangle = 1 \) to account for complex interaction topologies encoded in the matrix \( A \) as well as refractoriness and transmission delays.

III. GENERALIZED KINOUCHI-COPELLI MODEL

A. Description of the model

We will analyze a generalized version of the Kinouchi-Copelli model which includes possibly heterogeneous distributions of delays and refractory periods. The model is as follows:

- There are \( N \) excitatory elements, labeled \( i = 1, \ldots, N \).
- At discrete times \( t = 0, 1, \ldots \), each element \( i \) can be in one of \( m_i + 1 \) states, \( x_i^t \). The state \( x_i^t = 0 \) is the resting state, \( x_i^t = 1 \) is the excited state, and there may be additional refractory states \( x_i^t = 2, 3, \ldots, m_i \).
- If element \( i \) is in the resting state at time \( t \), \( x_i^t = 0 \), it can be excited in the next time step, \( x_i^{t+1} = 1 \), by another excited element \( j \) with delay \( \tau_{ij} \) (i.e., if \( x_j^{t-\tau_{ij}} = 1 \)) with probability \( A_{ij} \), or independently by an external stimulus with probability \( \eta \).
- The elements that are excited or in a refractory state, \( x_i^t \geq 1 \), will deterministically make a transition to the next refractory state if one is available, or return to the resting state otherwise (i.e., \( x_i^{t+1} = x_i^t + 1 \) if \( 1 \leq x_i^t < m_i \), and \( x_i^{t+1} = 0 \) if \( x_i^t = m_i \)).
- The coupling network, encoded by the matrix with entries \( A_{ij} \), is allowed to have complex topology.
B. Model dynamics

By considering a large ensemble of realizations of the above stochastic process on the same network, we can define the probability that node $i$ is at state $x_i$ at time $t$ as $p_i(x)$. The probabilities $p_i$ evolve in one step by

$$p_i^{t+1}(1) = p_i^t(0)r_i^t,$$
$$p_i^{t+1}(2) = p_i^t(1),$$

$$
\ldots
$$
$$p_i^{t+1}(m_i) = p_i^t(m_i - 1),$$

where $r_i^t$ in Eq. (2) is the rate of transitions from the ready to the excited state, given by

$$r_i^t = E \left[ \eta + (1 - \eta) \left( 1 - \prod_j (1 - A_{ij} p_j^{t-t_0}) \right) \right],$$

where $p_j$ is one if node $j$ is excited at time $t$ and zero otherwise, and $E[\cdot]$ denotes an ensemble average. Assuming that the neighbors of node $i$ being excited are independent events, we obtain

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

and we also have the normalization condition

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

where $r_i^t$ in Eq. (2) is the rate of transitions from the ready to the excited state, given by

$$r_i^t = E \left[ \eta + (1 - \eta) \left( 1 - \prod_j (1 - A_{ij} p_j^{t-t_0}) \right) \right],$$

where $p_j$ is one if node $j$ is excited at time $t$ and zero otherwise, and $E[\cdot]$ denotes an ensemble average. Assuming that the neighbors of node $i$ being excited are independent events, we obtain

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

and we also have the normalization condition

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

where $r_i^t$ in Eq. (2) is the rate of transitions from the ready to the excited state, given by

$$r_i^t = E \left[ \eta + (1 - \eta) \left( 1 - \prod_j (1 - A_{ij} p_j^{t-t_0}) \right) \right],$$

where $p_j$ is one if node $j$ is excited at time $t$ and zero otherwise, and $E[\cdot]$ denotes an ensemble average. Assuming that the neighbors of node $i$ being excited are independent events, we obtain

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

and we also have the normalization condition

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

where $r_i^t$ in Eq. (2) is the rate of transitions from the ready to the excited state, given by

$$r_i^t = E \left[ \eta + (1 - \eta) \left( 1 - \prod_j (1 - A_{ij} p_j^{t-t_0}) \right) \right],$$

where $p_j$ is one if node $j$ is excited at time $t$ and zero otherwise, and $E[\cdot]$ denotes an ensemble average. Assuming that the neighbors of node $i$ being excited are independent events, we obtain

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

and we also have the normalization condition

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

where $r_i^t$ in Eq. (2) is the rate of transitions from the ready to the excited state, given by

$$r_i^t = E \left[ \eta + (1 - \eta) \left( 1 - \prod_j (1 - A_{ij} p_j^{t-t_0}) \right) \right],$$

where $p_j$ is one if node $j$ is excited at time $t$ and zero otherwise, and $E[\cdot]$ denotes an ensemble average. Assuming that the neighbors of node $i$ being excited are independent events, we obtain

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

and we also have the normalization condition

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

where $r_i^t$ in Eq. (2) is the rate of transitions from the ready to the excited state, given by

$$r_i^t = E \left[ \eta + (1 - \eta) \left( 1 - \prod_j (1 - A_{ij} p_j^{t-t_0}) \right) \right],$$

where $p_j$ is one if node $j$ is excited at time $t$ and zero otherwise, and $E[\cdot]$ denotes an ensemble average. Assuming that the neighbors of node $i$ being excited are independent events, we obtain

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

and we also have the normalization condition

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

where $r_i^t$ in Eq. (2) is the rate of transitions from the ready to the excited state, given by

$$r_i^t = E \left[ \eta + (1 - \eta) \left( 1 - \prod_j (1 - A_{ij} p_j^{t-t_0}) \right) \right],$$

where $p_j$ is one if node $j$ is excited at time $t$ and zero otherwise, and $E[\cdot]$ denotes an ensemble average. Assuming that the neighbors of node $i$ being excited are independent events, we obtain

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t,$$

and we also have the normalization condition

$$p_i^t(0) = 1 - \sum_{j=1}^{m_i} p_j^t.$$
Now, we use the fact that the largest eigenvalue of $A$, $\lambda$, is typically much larger than the second eigenvalue,\textsuperscript{19,20} and thus $Ap \approx su$, where $s$ is a scalar to be determined and $u$ is the right eigenvector of $A$ corresponding to $\lambda$. The validity of this approximation will be discussed in Sec. VI C. With this substitution, the previous equation reduces to

$$su_k = \sum_{i=1}^{N} A_{ki} \frac{1 - (1 - \eta)e^{-su_i}}{1 + m_i - m_i(1 - \eta)e^{-su_i}}.$$  \hspace{1cm} (16)

Noting that

$$\hat{F} = \frac{\sum_{i,j} A_{ij} p_j}{\sum_{i,j} d_{ij}^\text{out}} \approx \frac{\sum_i su_i}{\sum_i d_{i}^\text{out}} = \frac{\langle u \rangle}{\langle d \rangle},$$

where $\langle \cdot \rangle \equiv \sum_{i=1}^{N} x_i/N$, we substitute $s \approx \hat{F}\langle d \rangle/\langle u \rangle$ into Eq. (16) yielding

$$\frac{\hat{F}\langle d \rangle}{\langle u \rangle} = \sum_{i=1}^{N} A_{ki} \frac{1 - (1 - \eta)e^{-\hat{F}\langle d \rangle/\langle u \rangle}}{1 + m_i - m_i(1 - \eta)e^{-\hat{F}\langle d \rangle/\langle u \rangle}},$$

which may now be summed over $k$, simplified, and solved for $\hat{F}$, yielding the scalar equation

$$\hat{F} = \frac{\langle d \rangle}{\langle u \rangle} \left[ 1 - \frac{1 - (1 - \eta)e^{-\hat{F}\langle d \rangle/\langle u \rangle}}{1 + m - m(1 - \eta)e^{-\hat{F}\langle d \rangle/\langle u \rangle}} \right].$$ \hspace{1cm} (17)

We note that in the notation above, the outer average $\langle \cdot \rangle$ corresponds to a sum over the index $i$ in Eq. (16). Given the adjacency matrix $A$, Eq. (17) can be solved numerically to obtain the response $\hat{F}$ as a function of $\eta$. We call Eq. (17) the “nonperturbative approximation” because its derivation does not rely on a perturbative truncation of the product term of Eq. (10), and we will numerically test its validity in Sec. VI, where we will find that Eq. (17) can be a good approximation for all values of $\eta$. In order to gain theoretical insight into how some features of the network topology and the distribution of the number of refractory states affect the response, we will use Eq. (17) to obtain analytical expressions for the response in various limits.

### B. Perturbative approximations

While the nonperturbative approximation developed in the last section provides information for all ranges of stimulus, it is useful to consider perturbative approximations, for example, to determine the transition point from quiescent to active behavior. We will obtain an approximation to $\hat{F}$ which is valid for small $\eta$ and $\hat{F}$. To do this, we expand the right hand side of Eq. (16) to second order in $s$ and first order in $\eta$ (as we will see, expanding to second order in $s$ is necessary to treat the $\eta \approx 0$ case) obtaining

$$su_k = \sum_{i=1}^{N} A_{ki} \left[ \eta(1 - su_i(1 + 2m_i)) - s^2 u_i^2 \left( \frac{1}{2} + m_i \right) + su_i \right].$$ \hspace{1cm} (18)

Multiplying by the left eigenvector entry $v_k$ and summing over $k$ we obtain, using $\sum_i A_{ki}v_k = \lambda v_k$ and rearranging,

$$\dot{s}^2 \left< vu^2 \left( \frac{1}{2} + m \right) \right> = \eta \lambda \langle v \rangle - sn \lambda \langle vu(1 + 2m) \rangle + (\lambda - 1)s\langle vu \rangle.$$ \hspace{1cm} (19)

In terms of $\hat{F}$, this equation becomes

$$\hat{F}^2 \langle d \rangle^2 \left< vu^2 \left( \frac{1}{2} + m \right) \right> \lambda = \eta \langle v \rangle \langle u \rangle^2 - \hat{F}(d) \eta \langle vu(1 + 2m) \rangle \langle u \rangle \times \langle u \rangle + (\lambda - 1)\hat{F}(d)\langle vu \rangle\langle u \rangle.$$ \hspace{1cm} (20)

To find the transition from no activity, $\hat{F} = 0$, to self-sustained activity, $\hat{F} > 0$, for vanishing stimulus, we let $\eta \rightarrow 0^+$ in the previous equation to find

$$\hat{F}_{\eta=0}(\lambda) = \left\{ \begin{array}{ll}
0 & \lambda < 1, \\
\frac{\lambda}{\lambda^2 - \langle vu \rangle^2} & \lambda \geq 1,
\end{array} \right.$$ \hspace{1cm} (21)

where the solution $\hat{F} = 0$ was chosen for $\lambda < 1$ to satisfy $\hat{F} \geq 0$. This equation shows that the transition from a quiescent network to one with self-sustained activity has, if the response $\hat{F}$ is interpreted as an order parameter, the signatures of a second order (continuous) phase transition. In addition, while the eigenvalue $\lambda$ determines when this transition occurs (at $\lambda = 1$), its associated eigenvectors $u$ and $v$ determine the significance of the observed response past the transition. If $\langle vu^2 \rangle \gg \langle vu \rangle \langle u \rangle$, for example, the response might be initially too small to be of importance. One aspect that was not considered in Ref. 2 is how the distribution of refractory periods affects the response. If the refractory periods $m_i$ are strongly positively correlated with the product $v_i u_i^2$, they can significantly increase the magnitude of the term $\langle mvu^2 \rangle$ in the denominator, decreasing the response. This can be intuitively understood by noting that this amounts to preferentially increasing the refractory period of the nodes that are more likely to be active (as measured by the approximation $p_i \propto u_i$, valid close to the critical regime), thus removing them from the available nodes for longer times.

The response $\hat{F}$ for small stimulus and response in Eq. (21) agrees with the perturbative expression derived for $\hat{F}$ directly from Eq. (9) in Ref. 2 if $m_i = 1$ and $\lambda \rightarrow 1$ and confirms the findings in Ref. 2 that the critical point is determined by $\lambda = 1$. Henceforth, we will refer to networks with $\lambda < 1$ as quiescent, to networks with $\lambda > 1$ as active, and to networks with $\lambda = 1$ as critical.

The behavior of the system for high stimulation is also of interest. When $\eta = 1$, node $i$ cycles deterministically through its $m_i + 1$ available states, and so $p_i = (1 + m_i)^{-1}$. The question is how this behavior changes as $\eta$ decreases from 1. This information can be extracted directly from Eq. (11) by linearizing around the solution $\eta = 1$ and $p_i = (1 + m_i)^{-1}$. Setting $\eta = 1 - \delta \eta$ and $p_i = \tilde{p}_i - \delta \tilde{p}_i$, with $\delta \eta \ll 1$ and $\delta \tilde{p}_i \ll \tilde{p}_i$, we obtain

$$\delta \tilde{p}_i \approx \tilde{p}_i^2 e^{-\sum_i A_{i,j} \delta \eta}.$$ \hspace{1cm} (22)

Thus, the response of the nodes to a decreased stimulus depends on a combination of their refractory period (which
determines $\tilde{p}_i$ and decays exponentially with the number of expected excitations from its neighbors. In terms of the aggregate response $\tilde{F}$, Eq. (22) becomes, after multiplying by $A_{ik}$, summing over $k$ and $i$, and normalizing,
\[
\frac{d\tilde{F}}{d\eta} = \frac{\langle d^{out} p^{out} e^{-\lambda^p} \rangle}{\langle d \rangle}.
\] \hspace{1cm} (23)

C. Dynamics near the critical regime

As in Ref. 2, we will study the transition from no activity to self-sustained activity in the limit of vanishing stimulus by linearizing Eq. (9) around $p_i^0 = 0$ for $\eta = 0$. Assuming $p_i^0$ is small, we obtain to first order
\[
p_i^{t+1} = \sum_{j=1}^{N} A_{ij} p_j^{t-\tau_j}. \hspace{1cm} (24)
\]
Assuming exponential growth, $p_i^t = z^t w_i$, we obtain
\[
z w_i = \sum_{j=1}^{N} A_{ij} z^{-\tau_j} w_j. \hspace{1cm} (25)
\]
The critical regime, determined as the boundary between no activity and self-sustained activity as $\eta \rightarrow 0$, i.e., between the solution $p_i^t = 0$ being stable and unstable, can be found by setting $z = 1$, obtaining
\[
w_i = \sum_{j=1}^{N} A_{ij} w_j. \hspace{1cm} (26)
\]
This implies that the onset of criticality occurs when $\lambda = 1$ and in this case $w = u$. This conclusion agrees with the results in Ref. 2 and those in Sec. IV B. Although the critical regime is not affected by the presence of delays or refractory states, the rate of growth (decay) $\nu$ of perturbations for the active (quiescent) regime depends on the distribution of delays. To illustrate this, we consider the case when the network deviates slightly from the critical state, so that the largest eigenvalue of $A$ is $\lambda = 1 + \delta \lambda$ and has right eigenvector $u$, $Au = (1 + \delta \lambda)u$. Expecting the solution $w$ to Eq. (25) to be close to $u$, we set $w_i = u_i + \delta u_i$ and $\nu = 1 + \mu$, where the rate of growth $\mu$ is assumed to be small. Inserting these in Eq. (25), we get to first order
\[
\mu u + \delta \lambda u \approx u \delta \lambda + A \delta u - \mu A u,
\] \hspace{1cm} (27)
where the entries of the matrix $A$ are given by $A_{ij} = A_{ij} \tau_j$. To eliminate the term $\delta u$, we left-multiply by the left eigenvector of $A$, $v$, satisfying $v^T A = (1 + \delta \lambda) v^T$. Canceling small terms, we get
\[
\mu \approx \frac{\delta \lambda}{1 + \frac{v^T A}{v^T u}}. \hspace{1cm} (28)
\]
If the delay is constant, $\tau_j = \tau$, we obtain
\[
\mu \approx \frac{\delta \lambda}{1 + \tau}. \hspace{1cm} (29)
\]
and in this particular case, a more general result can be obtained from Eq. (25), which implies $\lambda = \lambda^{1/(1+\nu)}$.

D. Relation to previous results

Here, we will briefly discuss how our results for the critical regime agree with previous work in particular cases. Correlations between degrees at the ends of a randomly chosen edge (assortative mixing by degree)\textsuperscript{8} can be measured by the correlation coefficient
\[
\rho = \frac{\langle d_i^{out} d_j^{out} \rangle}{\langle d_i^{out} \rangle}.
\] \hspace{1cm} (30)
defined in Ref. 19, with $\langle \cdot \rangle$ denoting an average over edges. The correlation coefficient $\rho$ is greater than 1 if the correlation between the in-degree and out-degree of nodes at the end of a randomly chosen edge is positive, less than one if the correlation is negative, and one if there is no correlation. For a large class of networks, the largest eigenvalue may be approximated\textsuperscript{19} by $\lambda \approx \rho \langle d_i^{in} d_i^{out} \rangle / \langle d_i \rangle$. In the absence of correlations, when $\rho = 1$, the largest eigenvalue can be approximated by $\lambda \approx \langle d_i^{in} d_i^{out} \rangle / \langle d_i \rangle$. If there are no correlations between $d_i^{in}$ and $d_i^{out}$ at a node (node degree correlations) or if the degree distribution is sufficiently homogeneous, then $\langle d_i^{in} d_i^{out} \rangle \approx \langle d_i \rangle^2$ and the approximation reduces to $\lambda \approx \langle d_i \rangle$. This is the situation that was considered in Ref. 1, and thus they found that the critical regime was determined by $\langle d_i \rangle = 1$. In the case of Refs. 4 and 7, with more heterogeneous degree distributions, $\lambda \approx \langle d_i^{in} d_i^{out} \rangle / \langle d_i \rangle$ applied, which accounts for their observation that the critical regime did not occur at $\langle d_i \rangle = 1$.

The situation encountered here is analogous to what occurs in the analysis of the transition to chaos in Boolean networks\textsuperscript{18} and in the transition to synchronization in networks of coupled oscillators\textsuperscript{21} where it is found that, instead of the mean degree, the largest eigenvalue is what determines the transition between different collective dynamical regimes.

Other previous studies in random networks have also investigated spectral properties of $A$ to gain insight on the stability of dynamics in neural networks\textsuperscript{22} and have shown how $\lambda$ could be changed by modifying the distribution of synapse strengths.\textsuperscript{23} In addition, it has been shown recently that the largest eigenvalues in the spectrum of the connectivity matrix may affect learning efficiency in recurrent chaotic neural networks\textsuperscript{24}.

V. DYNAMIC RANGE

We have studied the response of the network to stimuli of varying strengths. In particular, we studied in detail the response close to the critical regime. As has been previously noted,\textsuperscript{1} this regime corresponds to the point where the dynamic range $\lambda$ is maximized. In our context, the dynamic range can be defined as the range of stimulus $\eta$ that results in significant changes in response $\tilde{F}$. Typically, the dynamic range is given in decibels and measured using arbitrary thresholds just above the baseline ($\lim_{\eta \rightarrow -\infty} \tilde{F} = \tilde{F}_0$) and below the saturation ($\lim_{\eta \rightarrow +\infty} \tilde{F} = \tilde{F}_1$) values, respectively, as illustrated in Fig. 1 for the active network case $\tilde{F}_0 > 0$. 

\[ \]
which those approximations were developed, we will use refractory states on the dynamic range can be developed into the effects of network topology and the distribution of classically and the dynamic range calculated.

sponding to a given stimulus threshold can be found numerically or theoretically from Eq. (22), and we find it is so in our numerical examples when $m$ are not large (see Fig. 5). Taking $\eta_{\text{high}} = 1$ and $\eta_{\text{low}} = \eta^*$ we have

$$\Delta = -10 \log_{10}(\eta^*).$$

(32)

The stimulus level $\eta$ can be found in terms of $\hat{F}$ by solving Eq. (20) and keeping the leading order terms in $\hat{F}$, obtaining

$$\eta = \frac{\hat{F}^2 \langle d \rangle^2 \langle uu^* (\frac{1}{2} + m) \rangle - \hat{F} \langle d \rangle (\lambda - 1) \langle u \rangle \langle u u^* \rangle}{\hat{F} \langle v \rangle \langle u \rangle^2}.$$  

(33)

This equation shows that as $\eta \to 0$ the response scales as $\hat{F} \sim \eta$ for the quiescent curves ($\lambda < 1$) and as $\hat{F} \sim \eta^{1/2}$ for the critical curve ($\lambda = 1$). We highlight that these scaling exponents for both the quiescent and critical regimes are precisely those derived in Ref. 1 for random networks, attesting to their robustness to the generalization of the criticality criterion to $\lambda = 1$, the inclusion of time delays, and heterogeneous refractory periods. This is particularly important because these exponents could be measured experimentally. Using this approximation for $\eta^*$ in Eq. (32), we obtain an analytical expression for the dynamic range valid when the lower threshold $F^*$ is small. Of particular theoretical interest is the maximum achievable dynamic range $\Delta_{\text{max}}$ for a given topology. It can be found by setting $\lambda = 1$ in Eq. (33) and inserting the result in Eq. (32), obtaining

$$\Delta_{\text{max}} = \Delta_0 - 10 \log_{10} \left( \frac{\langle d \rangle^2 \langle uu^* (\frac{1}{2} + m) \rangle}{\langle v \rangle \langle u \rangle^2} \right).$$  

(34)

where $\Delta_0 = -20 \log_{10}(F^*) > 0$ depends on the threshold $F^*$ but is independent of the network topology or the distribution of refractory states. The second term of Eq. (34) suggests that a positive correlation between refractoriness $m$ and eigenvector entries $u$ and $v$ will decrease dynamic range, whereas a negative correlation will increase dynamic range. This prediction may be investigated in more depth in future publications. The second term of Eq. (34) also suggests that an overall increase in the number of refractory states will lead to an overall decrease in dynamic range. This is in contrast with the result of Ref. 25, which found that there exists a $m > 0$ which maximizes dynamic range in two-dimensional arrays of neurons. We note that the assumption of independence used in deriving Eq. (8) is not valid for a two-dimensional array.

VI. NUMERICAL EXPERIMENTS

We tested our theoretical results from Sec. IV by comparing their predictions to direct simulation of our generalized Kinouchi-Copelli model described in Sec. III. Simulation parameters were chosen specifically to test the validity of Eqs. (17), (23), (28), and (34). All simulations, except where indicated, were run with $N = 10^4$ nodes for $T = 10^5$ timesteps, over a range of $\eta$ from $10^{-3}$ to 1.

A. Construction of networks

We created networks in three steps: first, we created binary directed networks, $A_{ij} \in \{0, 1\}$, with particular degree distributions as described below, forbidding bidirectional links and self-connections; second, we assigned a weight to each link, drawn from a uniform distribution between 0 and 1; third, we calculated $\lambda$ for the resulting network and multiplied $\lambda$ by a constant to rescale $\lambda$ to the targeted eigenvalue. The two classes of topology considered for simulations were directed Erdős-Rényi random networks and directed scale-free networks with power law degree distributions, where we set the power law exponent to $\gamma = 2.5$, and enforced a minimum degree of 10 and a maximum degree of 1000. Erdős-Rényi networks were constructed by linking any pair of nodes with probability $p = 15/N$, and scale-free networks were constructed by first generating in-degree and out-degree sequences drawn from the power law distribution described above, assigning those target degrees to $N$ nodes.
and then connecting them using the configuration model. In some cases, an additional fourth step was used to change the assortativity coefficient $\rho$, defined in Eq. (30), of a critical (i.e., with $\lambda = 1$) scale-free network, making this network more assortative (disassortative) by choosing two links at random, and swapping their destination connections only if the resulting swap would increase (decrease) $\rho$. This swapping allows for the degree of assortativity (and thereby, $\lambda$) to be modified while preserving the network’s degree distribution.8,19

**B. Results of numerical experiments**

We first demonstrate the ability of the non-perturbative approximation to predict aggregate network behavior in a variety of conditions. Fig. 2 shows a multitude of simulations (symbols) with the predicted behavior of Eq. (17) overlaid (lines). The cases considered in Fig. 2 include different combinations of topology, assortativity, largest eigenvalue $\lambda$, delays, and number of refractory states. The number of refractory states $m_i$ was chosen either constant, $m_i = m$, or randomly chosen with equal probability among $\{1, 2, \ldots, m_{\text{max}}\}$. Similarly, the delays $\tau_{ij}$ were either constant, $\tau_{ij} = \tau$, or uniformly chosen with uniform probability in $(0, \tau_{\text{max}})$. The predictions capture the behavior of the simulations, with particularly good agreement for networks with neutral assortativity, $\rho = 1$. In the assortative and disassortative cases shown (cases (3) and (6) in Fig. 2), low and high stimulus simulations are well captured by the prediction, while a small deviation can be observed for intermediate values of $\eta$. The plots show excellent agreement between the prediction and simulation at many points in parameter space.

![Figure 2](image.png)

**FIG. 2.** (Color online) Semi-log plots of data from five simulations (symbols) testing a variety of situations in order to show the robustness of Eq. (17) (lines) to various sets of conditions: (1) Random network; $\lambda = 1$; mixed refractory states, $m_i \in \{1, 2, 3\}$; no delays; (2) Random network; $\lambda = 0.7$; no refractory states, $m_i = m = 1$; mixed delays, $\tau_{ij} \in \{0.1, 2.3\}$; (3) scale free network; $\lambda = 0.8$; disassortative rewiring; no refractory states, $m_i = m = 1$; no delays; (4) scale free network; $\lambda = 1.2$; uniform refractory states, $m_i = m = 2$; no delays; (5) Scale free network; $\lambda = 1.0$; mixed refractory states, $m_i \in \{1, 2, 3, 4\}$; mixed delays, $\tau_{ij} \in \{0, 1, 2\}$; (6) Scale free network; $\lambda = 1.2$; uniform refractory states, $m_i = m = 1$; no delays. The plots show excellent agreement between the prediction and simulation at many points in parameter space.

As reported previously, we find in our simulations that networks with $\lambda = 1$ show critical dynamics and exhibit maximum dynamic range. This applies to random networks, scale free networks, and scale free networks with modified assortativity. Networks with $\lambda < 1$ exhibit no self-sustained activity in the absence of stimulus, whereas networks with $\lambda > 1$ exhibit self-sustained activity. Furthermore, in all numerical experiments, with distributed refractory states and various time delays, the criticality of networks at $\lambda = 1$ was preserved as predicted above. Typical results in Fig. 3(a) show the response $\hat{F}$ as a function of stimulus $\eta$ for scale free networks with $\gamma = 2.5$, refractory states $m_i = m = 1$, and no time delays, with $\lambda$ ranging from 0.2 to 1.8. Each symbol in the figure is generated by a single simulation on a single network realization. Lines show $\hat{F}$ obtained from numerical solution of Eq. (17). We note that the simulations with $\lambda = 1$ show a deviation from the theoretically predicted critical curve for values of $\eta$ less than $10^{-4}$. We believe this is due to the fact that for such low values of $\eta$, a much longer time average than the one we are doing would be required. For example, with $\eta = 10^{-5}$ we expect that, using $10^5$ time steps, a given node will not be excited externally with probability $e^{-1} \approx 0.37$. This might be especially important in the critical regime, where activity is mostly determined by sporadic avalanches propagated by hubs.

Figure 3(b) shows the dynamic range $\Delta$ calculated using $F^* = 10^{-2}$ directly from the simulation (circles) and using Eq. (17) (dashed line). As demonstrated in Ref. 2, the dynamic range is maximized when $\lambda = 1$. We note that in Ref. 2, the dynamic range was estimated using a perturbative approximation and as a consequence, our prediction had a systematic error in the $\lambda > 1$ regime [cf. Fig. 1(b) in Ref. 2]. The nonperturbative approximation Eq. (17) results in a much better prediction.

Figure 4 shows the transition that occurs at $\lambda = 1$ when $\eta \rightarrow 0$ for experiments with a varying number of refractory states, $m = 1, 3$, and 5. Symbols indicate the results of direct simulation using $\eta = 10^{-5}$ and the lines correspond to Eq. (17), which describes well the result of the simulations. We found that for this particular network, the perturbative approximation (21) only gives correct results very close to the transition at $\lambda = 1$, and its quantitative predictions degrade quickly as $\hat{F}$ grows. [A similar situation can be observed in Fig. 2(b) of Ref. 2.] However, we found that the perturbative approximation is still useful to predict the effect
of the refractory states. Equation (21) predicts that the response should scale as 
\[ h^{m+1/2}/C_0 \]

The inset shows how, after multiplication by 
\[ h^{m+1/2}/C_0 \]
the response curves collapse into a single curve. Figure 4 also depicts a linear relationship,
\[ ^\wedge F/C_24(k/C_0 k_c) \]
for \( k > 1 \). Making a connection with the theory of nonequilibrium phase transitions in which
\[ ^\wedge F/C_24(k/C_0 k_c) \]
b, we derive \( k_c = 1 \) and the critical exponent \( \beta = 1 \).

\[ ^\wedge F \]

Figure 5 shows the response \(^\wedge F\) close to \( \eta = 1 \) calculated for various values of \( m \) from the simulation (symbols), and from Eq. (23) (solid lines). Equation (23) describes well the slope of \(^\wedge F\) close to \( \eta = 1 \). An important observation is that as \( m \) grows, the relative slope \( ^\wedge F^{-1}dF/d\eta \) at \( \eta = 1 \) decreases. Therefore, if the typical refractory period \( m \) is large, the response \(^\wedge F\) saturates [e.g., reaching 90% of \(^\wedge F(1)\)] for smaller values of \( \eta \).

Transmission delays, as in the analogous system of gene regulatory networks, do not modify steady state response. However, delays modify the time scale of relaxation to steady state. We quantified this modification in the growth rate in Eq. (28), which determines the growth rate of perturbations from an almost critical quiescent network in terms of a matrix

\[ N = 100000 \text{ nodes and} \quad \eta = 10^{-6}, \quad \text{for (1) } \lambda = 1.1, \tau = 0, \text{ (2) } \lambda = 1.2, \tau = 0, \text{ (3) } \lambda = 1.1, \tau \in \{0, 1, 2, 3\}, \text{ and (4) } \lambda = 1.2, \tau \in \{0, 1, 2, 3\}. \]
determined from the distribution of delays. In Fig. 6, we show time series (solid lines) for the initial growth in the number of excited nodes within four active networks with and without time delays. For comparison, we show the slope that results from the corresponding growth rates obtained from Eq. (28) (dotted lines). The timesheds shown on the horizontal axis have been shifted to display multiple results together, but not rescaled or distorted. As shown in Fig. 6, Eq. (28) is helpful in quantifying the growth rate of signals within the network in the regime during which growth is exponential. In this limited regime, simulation data compare well with time series of excitations and capture the growth rate’s dependence on eigenvalue and time delays. We note here that Eq. (28) predicts the growth rate of $p_i^*$, and, therefore, the growth rate of both $f^*$ and $\tilde{f}$. Here, we have chosen to show the growth in the number of excited nodes (proportional to $f^*$) which is more experimentally accessible than $f^*$. 

C. Validity of the approximation $Ap \propto u$

Here, we will address the question of the validity of our approximation $Ap \propto u$, which was used to develop the nonperturbative approximation Eq. (17). First, we note that when $\eta$ and $p$ are small, the linear analysis of Sec. IV C and Ref. 2 shows that $p \propto u$, and, therefore, the approximation $Ap \propto u$ is justified in this regime. As $\eta$ grows, and for situations where $p$ is not small, one should expect deviations of $p$ from being parallel to $u$. However, we note that because $p_i$ measures how active node $i$ is, it should still be highly correlated with the in-degree of node $i$. Because in many situations the in-degree is also correlated with the entries of the eigenvector $u$, we expect that in those cases $p$ remains correlated with $u$. After multiplication by $A$, the approximation can only become better. For the class of networks in which the ratio between the largest eigenvalue $\lambda$ and the next largest eigenvalue scales as $\sqrt{\langle d \rangle}$ (which include Erdős-Rényi and other networks), we expect that $Ap \propto u$ should be a good approximation.

Another reason why the approximation $Ap \propto u$ works well even when $F$ is not small is that the errors introduced by this approximation vanish exactly when $\eta = 1$. To see this, note that for $\eta = 1$, because each node cycles deterministically through its $m_i + 1$ available states, we have $p_i = 1/(1 + m_i)$, which gives $F = \sum_{i,j} A_{ij} (1 + m_j)^{-1} \sum_{i,j} A_{ij} = \langle d^{out}(1 + m)^{-1} \rangle / \langle d \rangle$, which agrees exactly with the result of setting $\eta = 1$ in Eq. (17). Thus, even as the assumption $Ap \propto u$ may become less accurate as $\eta$ grows, the importance of the error introduced by it decreases and eventually vanishes at $\eta = 1$.

To illustrate how the assumption $Ap \approx su$ works in some particular examples, Fig. 7 compares normalized $Ap_i$ and $u_i$ for a variety of eigenvalues and stimulus levels. Good agreement between them (characterized by a high correlation) indicates that the assumption of Sec. IV A is valid, whereas more noisy agreement for some cases indicates that the assumption $Ap \propto u$ is invalid (although, as discussed above, this does not necessarily imply that the nonperturbative approach will fail). Low stimulus levels in quiescent networks (top left panel) show relatively low correlation for short simulations, but the correlation improves with more timesteps as relative nodal response increases at well connected nodes and decreases at poorly connected nodes. Assortative networks (bottom panels) show slightly lower correlation as well, corroborating the results shown in Fig. 2 where the predictive power of Eq. (17) is slightly diminished for the assortative network. As expected, correlation between $Ap$ and $u$ entries is worst at $\eta = 1$ (right panels), but we reiterate that for $\eta = 1$ this error does not affect the predictions of Eq. (17).

VII. DISCUSSION

In this paper, we studied a generalized version of the Kinouchi-Copelli model in complex networks. We developed a nonperturbative treatment [Eq. (17)] that allows us to find the response $F$ of the network for a given value of the stimulus given a matrix of excitation transmission probabilities $A$. Our approach includes the possibility of heterogeneous distributions of excitation transmission delays and numbers of refractory states. An important assumption in our theory is that there are many incoming links to every node, which allows us to transform the product in Eq. (9) into an exponential. This assumption is very reasonable for neural networks, where the number of synapses per neuron is estimated to be of the order of 10000. In addition, in order to obtain a closed equation for $F$, we assumed $Ap \propto u$. As discussed in Sec. VI C, this approximation works well in the regime when the response and stimulus are small. Furthermore, the error introduced by this approximation becomes smaller as the probability of stimulus increases and eventually vanishes for $\eta = 1$. The result is that Eq. (17) predicts the response $F$ satisfactorily for all values of $\eta$. While we validated our predictions using scale-free networks with various correlation properties, we did not test them in...
topologies in which mean-field theories have been shown to fail, such as periodic hypercubes and branching tree networks. This study is left to future research.

Our theory describes how the introduction of additional refractory states modifies the network response by modifying Eq. (17). In addition, their effect is captured by the perturbative approximations of Sec. IV B which, although valid in principle only for very small $F$, we have found successfully predict the effect of a distribution in the number of refractory states for a larger range of response values.

We studied the effect of time delays on the time scale needed to reach a steady-state response and found that Eq. (28) determines the growth rate of perturbations from a quiescent, almost critical network. The temporal characteristics of the response could be important in the study of sensory systems, in which the stimulus level might be constantly changing in time. Additionally, delays may be important in studying the phenomenon of synchronization and propagation of wavefronts, which we do not study here. Synchronization in epidemic models similar to the model considered here has been well-described in the absence of time delays, and synchronization in Rulkov neurons has been shown to be affected subtly by time delays. However, the effect of time delays on synchronization in our model remains an open line of inquiry.

An important practical question regarding the application of our theory to neuroscience is how our results can be extended to networks with a large number of neurons. The Kinouchi-Copelli model we are using, and similar models used successfully by neuroscientists to model neuronal avalanches, have therefore considered only excitatory neurons, while adjusting the probabilities of excitation transmission to account for different balances of excitatory and inhibitory neurons. Nevertheless, we believe a generalization of the Kinouchi-Copelli model that accounts for inhibitory connections should be investigated in the future.

Another important issue is the generality of our findings for more biologically realistic excitable systems. We conjecture that the effect of network topology on the dynamic range of networks of continuous-time, continuous-state coupled excitable systems such as coupled ordinary differential equation (ODE) neuron models is qualitatively similar to its effect on the class of discrete-time and discrete-state dynamical systems studied here. However, this remains open to investigation.
